*We presented earlier versions of this paper at the Midwest Political Science Association Annual Meeting, Chicago, Ill., April 22, 2010, and at the Annual Meetings of the American Political Science Association, Toronto, Canada, September 2-5, 2009. This project is funded by a grant from the Digital Government Program of the NSF (award number IIS-0429452). We gratefully acknowledge the intellectual contributions from our colleagues at the Congressional Management Foundation (CMF), especially Collin Burden, Nicole Folk-Cooper, Kathy Goldschmidt, and Tim Hysom. We thank Daniel Butler, Barbara Trish, Caroline Tolbert, and Paul Zak for very helpful comments. Any opinions, findings, and conclusions or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of the NSF or CMF.
Abstract

Legislative websites are increasingly important in the practice of representation. We test whether legislative offices learn website representation practices from each other, using data from the 2006 and 2007 official home pages of members of the U.S. House of Representatives. We find that web design practices regarding the content of legislative websites diffuse within state delegations, that is, among members hailing from the same state, but the underlying website technologies do not. By contrast, website features do not appear to diffuse through cross-state communication channels such as cosponsorship networks or cueing processes based on ideological proximity. These contrasting results suggest the continued importance, even in the online world, of state delegations in congressional representation.
1 Introduction

The practice of representation is central to any legislator’s responsibilities, both normatively (Pitkin, 1967) and empirically (Fenno, 1978). The relatively recent development of Internet-based communication technologies has the potential to transform the way legislators engage in the practice of representation (Druckman, Hennessy, Kifer and Parkin, 2009; Druckman, Kifer and Parkin, 2007). In the U.S., citizens are increasingly turning to the official web-pages of members of Congress to learn about their policy positions and constituency service activities.¹ Online representation requires members to post timely and relevant content, and to deploy technology that improves access to the content.

As with technological innovation in any occupational field, legislators must learn how to adopt and implement these new online communication technologies in order to realize the potential advantages in reaching out to constituents and others. In this paper, we examine whether members of the U.S. Congress learn online representation practices from each other, focusing on the extent of diffusion of website design features among representatives’ official homepages. It is well known within the literature on Congress that members often discuss practices of representation with other members within their state delegation (e.g., Padgett, 1990; Truman, 1956). We therefore expect that a member will be more (less) likely to adopt new website content and technology design features if other members of her state delegation have (have not) adopted the features (Kingdon, 1989, 88-91).

A major inferential issue in testing the effects of a geographically-concentrated small group on technology diffusion, or diffusion among physically proximate units, is to distinguish a causal diffusion process driven by membership in the group from a process driven simply by unmeasured (latent) confounding attributes that members of the social grouping happen to have in common (see Fowler, Heaney, Nickerson, Padgett and Sinclair, N.D.; Lazer, 2001). Using data on the website designs of neighboring congressional districts, some of which are across state lines, we are able to control for unobserved local level confounding variables, and so we can identify the causal effect of membership in a state delegation on website design.
Our results suggest that the state delegations play an important role in the diffusion of website design among congressional offices. The dependence we observe, however, involves a design focus on content rather than on the underlying technology of the websites. Website design features do not appear to diffuse through potential cross-state communication channels between members, such as cosponsorship networks (Fowler, 2006; Fowler and Cho, 2010) or via a cueing process based on ideological proximity (Kingdon 1989, 74; Krehbiel 1992, 81). To the extent it exists, then, the diffusion of online representation practices appears to be driven by small group processes within state delegations, rather than through substantive policy discussion channels that cross state lines.

2 State Delegations and the Diffusion of Website Representation Practices

The social networks literature has identified social conditions that foster the diffusion of innovations (Coleman, Katz and et al, 1957; Hagerstrand, 1967; Ryan and Gross, 1943). Social network research has found that strong or “high bandwidth” relationships that often exist within small group – those based on personal familiarity, trust, and high frequency – are especially important in the diffusion of innovations (Allen, 1978; den Bulte and Moe-naert, 1998; Festinger, 1950; Hansen, 1999; Kraut, Egido and et al, 1990; Monge, Rothman and et al, 1985; Rice and Aydin, 1991; Zahn, 1991). Learning through observing others’ experiences lowers the ambiguity and perceived risk associated with an innovation (Galaskiewicz and Burt, 1991; Haunschild and Milner, 1997; Valente, 1995). Further, the behaviors of others within a small group or a social network creates a normative environment. A behavior is legitimate because others who are similarly situated are doing it, inducing mimetic isomorphism (DiMaggio and Powell, 1983).

In this paper, we test whether diffusion of website design occurs through state delegations. Scholars have long recognized (Deckard, 1972; Kessel, 1964; Padgett, 1990; Truman, 1956) the tendency of members from the same state to meet and discuss legislative policy and
process.\footnote{Kingdon (1989, 88-91) describes two mechanisms for influence among delegation members. First, members from the same state often know each other personally, often for extended periods, have friends in common, and as a result have more trust in each other.\footnote{Second, state delegation members often have incentives to act cohesively, and not to stand out from the group. As a result, delegation members are more likely to mimic each others’ websites, to ask each other for advice, or to hire common outside web design firms.} We therefore expect to discover dependence among the websites among members from a common state delegation, or the small group cohesion that Truman (1956), Deckard (1972), Padgett (1990) and Kingdon (1989) observed for voting decisions. Note that we do not attempt to identify the mechanism or mediating variables through which state delegation membership has a causal effect. In particular, we are agnostic whether diffusion occurs as a result of communication within the delegation; one also would observe this dependence with mimetic or competitive processes (DiMaggio and Powell, 1983). Identifying this sort of mediating causal effects, even under the best of circumstances, requires very strong assumptions (Imai, Keele, Tingley and Yamamoto, 2010). Instead, we seek to identify and estimate the “black box” causal effect of state delegation membership on the diffusion of online representation. Identifying this causal effect requires that we account for similarities among websites that is due to the group members’ spatial or geographic proximity. To show the causal effect of membership in a state delegation requires that we hold constant all other commonalities members might have, other than belonging to the same delegation, by virtue of their geographic proximity, such as having similar constituencies, districts, and political orientation.}

3 Preliminary Evidence from Survey Findings

There has been very little research on the potential influence of small groups and social networks within the US Congress.\footnote{To motivate a more systematic analysis later in the paper, and to justify our focus on state delegation networks, in this section we make use of...}
a survey we conducted in winter, 2007, of the Congressional staff in charge of the members’ official websites. Out of 440 offices surveyed, we received 100 responses (23 percent).⁶

In the survey, we asked respondents, “Among other Members of Congress’ websites, are there ones that stand out to you as especially good? If yes, which do you think are particularly good?” Fifty two websites were named, some multiple times. Of those 52, 86 percent were within the same party, and (when combined with 11 responses indicating the state delegation), 60 percent were within the same state delegation.⁷

We use these data and random effect logit regression to estimate the change in the probability that one members’ staff would mention another member’s website. For covariates, we use Same party indicating both the “mentioner” and “mentionee” are in the same party, and Same state indicating both are in the same state delegation. To capture any effect from cueing processes based on policy agreement (Kingdon, 1989), we include the difference in first dimension DW-Nominate scores (http:\www.voteview.com). We also include the number of cosponsorships common between both members as an alternative, policy-based communication network by which technology practices may diffuse (Fowler, 2006).⁸ We grouped the random effect on the mentionee to control for any additional unobserved (confounding) variables that tend to increase the overall probability a mentionee website is mentioned.

The logistic regression confirms that state delegation was a powerful predictor that one office would name another (p = 0.045). The difference in DW-Nominate scores, capturing ideological distance, has a negative point estimate as one would expect, but the estimate is not significant (p = 0.711). The effect of sharing cosponsorships, which may indicate an institutional collegiality between two offices, also has no discernible effect (p = 0.830). Taken together, these findings indicate that staffers themselves, at least in this subsample, believe they learn from the practices of others in their own state delegation, but perhaps not through other policy communication channels such as cosponsor networks (Fowler, 2006) or via ideological cueing processes (Kingdon, 1989, 74).

Also important were whether both offices were from the same party (p = 0.030). How-
ever, in the analysis that we present below we cannot distinguish party as a social network or grouping from party as an institution, since parties are both formal and informal organizations. To capture any change in probability of website design practices due to the legislative parties, we simply include a dummy party variable in the statistical model. Note that the presence or absence of a party effect does not imply the presence or absence of party effects of within-party diffusion. For example, if some website feature diffuses within both parties equally, the fixed effect of party would appear to be zero.

4 Data

Within the U.S. House of Representatives, congressional offices are 440 (including nonvoting delegates) small, functionally identical, public organizations with a set of policy and procedural outputs (Hedlund, 1984; Salisbury and Shepsle, 1981). This enables a large N statistical study of members’ adoption of new practices in online representation. Web technology was changing rapidly in this time period, and so we do not offer this analysis as a journalistic account of contemporary web practices. Instead, we argue that examining the dynamics of web practices as they emerged is useful as a case study of how legislators adapt their representation practices to technology at a time when the state of the technology is in flux (Bimber, 2003, 8).

In this section we describe our measures of website design features, how we created the district adjacency and state delegation matrices, our strategy for identifying the causal effects of state delegation given these data, and some covariates (Druckman, Kifer and Parkin, 2007; Esterling, Lazer and Neblo, 2005) that also are of substantive interest.

4.1 Outcome variables: Measuring online representation

The dependent variables we use for this analysis are drawn from the 2006 and 2007 Congressional Management Foundation (CMF) coding of the official web site for each member of
Congress (for similar coding efforts, see Druckman, Kifer and Parkin, 2007; Johnson, 2004; Owen, Davis and Strickler, 1999; Stromer-Galley, 2000). In the summers of 2006 and 2007, CMF staff coded each official website. CMF trained teams of coders, who accessed and coded each official website based on nearly 100 operational criteria. CMF identified and defined the criteria using a number of sources regarding best practice standards for legislative websites, specifically by asking focus groups of citizens to spend time on a sample of sites, interviews and surveys with office staff and citizens, and by conducting web industry research (Johnson, 2004). This field research established standards for the practice of online representation, focusing on policy content, constituency services, and relevant technology (Burden and Hysom, 2007).

The coding for the 21 variables we use for this study, and the instructions given to the coders, are listed in appendix table A1. The descriptive statistics for the coded variables are listed in table 1, separately for the 2006 and 2007 panels. The appendix also reports on our analysis of intercoder reliability and the validity of the coding rules.

[Table 1 about here.]

The dataset includes four items that measure the presence and quality of policy-relevant issue information on each site. These are coder ratings of the quality of information regarding national issues, state and local issues, and issues of special importance to the member; and the presence of rationales that help explain the member’s voting decisions.

We use seven items to measure the overall quality of constituency services on the website. These include coders’ rating of the quality of casework FAQ answers, the presence of information on how to initiate casework with the member’s office, whether the website includes an online casework initiation form, and the presence of links to federal agencies and to FirstGov.gov (now www.usa.gov), and information about local district resources and services.

For items measuring the technical quality of each website, we include measures of whether or not the site contains video, audio, has a text only option, a blog, an RSS feed, and podcast
capabilities. The final three items measure general technical properties of the website design, its navigability, its readability, and its timeliness, each measured on a five point scale.

4.2 State delegation and alternative adjacency measures

Following the discussion above, we expect membership in a state delegation to have an influence on members’ decision to adopt the online representation practices described in table 1. To account for members’ state delegations, the statistical model we use requires that we construct an “adjacency matrix,” in which two members are “adjacent” if they belong to the same state delegation. We constructed this adjacency matrix with rows representing members, columns with labels identical to the rows, cells \([i, j]\) equal to one if members in row \(i\) and column \(j\) are in the same state, and cells equal to zero if members \(i\) and \(j\) are in different states.\(^\text{10}\) The diagonal of this matrix is a zero vector. Our random effect model also requires a matrix of district adjacencies. This matrix is similar to the state delegation matrix, with the exception that the cells are equal to one if two members’ districts are adjacent, and zero otherwise.\(^\text{11}\)

For comparison, we also estimate the model below substituting an adjacency matrix constructed from cosponsorship data (Fowler, 2006). The labels of the cosponsorship matrix are identical to those of the district and state delegation matrices, with zero on the diagonal, and off diagonal elements of the \(i^{th}\) row equal to one if member \(i\) and member \(j\) were frequent cosponsors, where “frequent” is more than one standard deviation above the mean number of \(i\)’s cosponsorships with all members. To test for possible diffusion through cueing processes (Kingdon, 1989), we also estimate the model substituting an adjacency matrix where the off diagonal elements are one if member \(i\) and member \(j\) are close to each other in DW-Nominate space (http://www.voteview.com). We define two members as “close” in DW-Nominate space by first squaring the deviation between member \(i\) and all other members, and then selecting the subset members that are in the lowest 12.5 percentile in distance from member \(i\).\(^\text{12}\)
4.3 Identifying the Causal Effect of Belonging to a Spatially-Defined Group

The major inferential issue in testing hypotheses about diffusion among geographically-proximate units involves distinguishing a diffusion process within the geographically concentrated small group from mere spatial heterogeneity (Congdon 2003, 274; Lazer 2001). That is, if the websites of the members of a state delegation are all likely to have a given characteristic, and websites in another state are unlikely to, we wish to be able to test whether this correlation is due to a causal diffusion process, or due to a spurious dependence where many members of a state delegation may happen to share an unobserved causal variable.

In the statistical analyses below, we are able to control for spatial heterogeneity by exploiting data from several members whose congressional districts are adjacent to each other. If spatially confounding variables exist, they would most likely be evident in these localized clusters, since adjacent congressional districts, even those across state lines, often share more similarities than districts at opposite ends of a state. For example, the California 45\textsuperscript{th} district (including the desert cities of Palm Springs and Indio) shares more similarities with the California 44\textsuperscript{th} district (Riverside and Corona) and with the Arizona 7\textsuperscript{th} district (parts of Yuma, Maricopa and Pima desert counties) than with the California 6\textsuperscript{th} district (wine country, Marin and Sonoma counties). Evidence is lent in support of the causal effect of state delegation on diffusion if members’ web design practices are observed to be dependent within groupings defined by state delegation after having controlled for district-level spatial heterogeneity.

One can think of this approach as similar to a random effect model, where the adjacent districts serve as “repeated observations” for a given district. The design of these “repeated observations” allow us to estimate the latent propensity of someone representing the district to have each design feature, by virtue of representing that locality. Holding this latent propensity constant, the design of the state delegation websites represent the members’ exposure to a causal variable of interest.
The persuasiveness of this quasi-experimental approach depends on the ignorability of state boundaries for unobserved spatially distributed confounding variables. Ignorability requires that the conditional distributions of any unobserved causal variables across districts that are geographically proximate, but on either side of the state line, are similar. For example, this assumption holds that residents in Calumet City, Illinois (IL-2, in southeast Chicago), are similar to those who live in nearby Gary, Indiana (IN-1), and members that serve in each each of these districts share similar qualities. One would also expect that each of these will differ demographically and politically from those in New Albany, Indiana (IN-9, near Louisville).

We can test for the ignorability of state boundaries using aggregate district level census data. If state borders are ignorable, then variables constructed from aggregate census data should be balanced between districts that are on either side of the state border, among those that are adjacent to a district that lies on a border. At the same time, one would not expect census data to be balanced between adjacent districts and those within the state but not adjacent. We test balance only among the 242 districts that lie adjacent to a border and that are in a state large enough to have districts that are within the state but not adjacent (55 percent of districts in the sample meet these conditions). For covariates we use census data on district median income; the percent of the district residents that are college educated; in the service employment sector; the blue collar sector; the white collar sector; under 18; over 64; Black; and the percent voting for Kerry in the 2004 general election. In addition, the attributes of the members from these districts also should be ignorable. For the member attribute variables, we use the number of terms each has served, and the first and second dimension \textit{DW-Nominate} score (see \url{www.voteview.com}). Using the omnibus balance test statistic of Hansen and Bowers (2008), we cannot reject the hypothesis of balance between adjacent districts ($p = 0.307$), but we can reject the hypothesis of balance between within-state non-adjacent districts ($p < 0.0001$). That the adjacent districts are balanced at the local level justifies using adjacent districts as “repeated observations” in a random effect
model, as a method to hold constant district-level unobservable variables, and so to identify the causal effect of membership in a state delegation.

4.4 Control variables

Since our model is designed to hold all district-level covariates constant through a random effect, we do not need to include a long battery of district or member level covariates. Instead, we hold constant only two variables that previous work (e.g., Esterling, Lazer and Neblo, 2005) found to have an effect on the quality of legislative websites and that are of substantive interest to this paper. First, as we note above, staff themselves report attending to websites within their party, and this suggests the possibility of party effects. We control for the member’s political party by including a variable that equals one if the member is a Republican (the majority party in 2006) and zero otherwise (mean 0.533, standard deviation 0.499). Second, members who have longer terms in office tend to make less effective use of website technology. To control for this, we include a measure that equals one if the member is a Freshmen in 2006 and zero otherwise (mean 0.096, standard deviation 0.295).

5 Estimation

We hypothesize that a member’s use of website design features depends on the propensity of other members in her state delegation to also adopt those features, and these other members themselves are in the same estimation sample. The statistical literature on geographically connected processes has devised techniques to study spatial inter-dependencies in a way that appropriately accounts for these reciprocal effects (Anselin, 1988; Cliff and Ord, 1981; Doreian, 1980). For this paper we estimate spatial dependence with a conditionally autoregressive (CAR) model (Congdon, 2003, chapter 7) using Bayesian MCMC sampling to simulate a posterior distribution of all model parameters.

We describe the model in detail in the appendix (for the model, we rely on Congdon,
In summary, the model includes the covariates in the outcome equation, and holds constant any remaining relevant local level variables constant via a random effect that groups members using the district adjacency data. The random effect is captured in a structural parameter we label $\rho_a$. Holding these local level variables constant, the model tests for the effect of membership in a state delegation by grouping members using the state delegation data, an effect that is captured in a structural parameter we label $\rho_s$.

We estimate the model in four ways.

1. Assuming the relevant state delegation for member $i$ contains all other members in her state.

2. Assuming that the relevant state delegation for member $i$ contains only other members in her state that are of the same party, or same state copartisans. For the few members with no copartisans in the state, we assume that the full state delegation is the relevant reference group.

3. Substituting the adjacency matrix constructed from cosponsorship data (described above) for the state adjacency matrix. For this model, we omit the local level (district adjacency) random effect from the outcome equation. If $\rho_s$ in this model is positive, we cannot distinguish between a causal diffusion within the cosponsorships network and latent dependence due to omitted local level variables. If $\rho_s$ is not positive, then we can conclude there is no evidence of dependence, causal or otherwise, within cosponsorship networks.\(^{15}\)

4. Using the same models as in 3, but this time substituting the DW-Nominate adjacency matrix. The same caveats regarding causality apply to this model that apply to model 3, above.

We estimate all four of these models first assuming cross sectional dependence, modeling member $i$’s propensity to have the website feature in the 2006 data as a function of other
members’ propensity to have the same feature in 2006. To test whether there is a time lag in adoption decisions we also model member $i$’s propensity to have the feature in 2007 as a function of other members’ propensity to have the feature in 2006. Since an election intervened between the 2006 and 2007 panels, we set the 2007 outcomes of 2006 incumbents who did not return in 2007 to missing, and impute their 2007 outcomes under missing at random conditional on the fixed and random effect variables using the method of Tanner and Wong (1987).

For estimation, we use the MCMC Gibbs sampler in WinBUGS (Spiegelhalter, Thomas, Best and Gilks, 1996). We assume diffuse priors for the structural parameters to minimize the influence of the prior parameter distributions on the posteriors. We sample three chains and initialize each chain with overdispersed starting values. The chains show extremely good mixing using the Brooks-Gelman-Rubin diagnostic (Gelman and Rubin, 1992). Below we present summaries of the marginal posterior distributions of the model parameters.

6 Findings

One advantage of Bayesian estimation is that the results are reported as a posterior distribution. One can use the posterior distribution to evaluate the significance of parameter estimates without relying on strict (frequentist) hypothesis tests. The results for models using the 2006 cross sectional data are in table 2. The cell entries indicate the probability of dependence for each outcome variable among members of a state delegation, holding constant local level unobserved variables and the control variables. That is, each cell gives the density of the posterior probability distribution of the $\hat{\rho}_s$ parameter, or the structural parameter that captures dependence within state delegations, that lies above zero.

The bottom row of table 2 indicates the number of items that have at least a 90 percent probability of dependence within each network. Notice that by this criteria, dependence is most likely within the same state network (dependence for nine items), and this dependence
is not amplified when the state delegation is restricted only to co-partisans (dependence for only five items). There appears to be dependence within state delegations among a wide range of items, including those measuring issue representation (content on national issues, the member’s priority issues, and her vote rationales), constituent needs (help with casework initiation), the technical qualities of the websites themselves (audio, a text only feature), and the general technical qualities of websites (navigability, readability, and timeliness).

Figure 1 depicts the magnitude of the diffusion effects for six of the items for which diffusion was present in 2006. The dark line in each graph shows how the estimated change in probability that member $i$ adopts a design element changes as the proportion of her state delegation who also adopt that element increases (the light lines are random draws of parameter sets from the posterior distribution and hence depict the uncertainty for each conditional probability, similar to a confidence interval). The “rug” in each figure shows the actual range of the proportion across state delegations, so estimates beyond the rug are out of sample.

The top four graphs in figure 1 indicate diffusion effects for quality of website content such as issue positions, vote rationales, and casework FAQs. For these measures, a one indicates the website was judged by the coder as having good quality and specific content on each of the dimensions. The probability that a member has high quality content when everyone else in the state had low quality content ranges from about 0.2 to about 0.4. For the national issues, member’s issues and casework FAQs items, the actual proportion of the state delegations with high quality content varies from zero to nearly one. Varying this proportion increases the propensity to have good quality national issue content by about 60 percentage points, member’s issues by about 20 percentage points, and casework FAQs by about 40 percentage points, where each of these differences is statistically significant. In the sample, only about half of the state delegations had vote rationale content on their
websites, but extrapolating outside of the sample indicates the diffusion effect is about the same magnitude as for the other content items.

The bottom two graphs depict two elements of website technology that show positive diffusion. In contrast to the four content items, the probability that a member has audio or text only technology on their websites if no one else in their delegation has the technology is essentially zero. The range of the actual proportion of state delegation who also adopt these technologies varies only from zero to about half. Within this range, the propensity for a member to adopt one of these communication technologies increases, but only imperceptibly. In comparing these to the first four graphs, it is apparent that most of the diffusion within state delegations centers on content-related design rather than on the underlying communication technology of the website.

Returning to table 2, the entries in the second column indicate that dependence within the state delegation does not seem to be heavily conditioned on partisanship. The probability of diffusion is constant whether or not one takes into account partisanship within the delegation. This finding is consistent with Truman (1956, 1034) who notes that partisan divides are relatively absent in discussions among members of a state delegation. No dependence is evident within the cosponsorship network or within the network defined by ideological proximity. The second to last row indicates this pattern does not change when one relaxes the criteria to only a 75 percent probability. These findings suggest that most of the social influence within the institution is within state delegations as a whole, perhaps as true today as it was in the time of Truman (1956). That geographic state delegation networks appear to matter more than DC-based legislative networks such as coponsorship or ideological distance is perhaps to be expected. The main purpose of the website is for the member to represent herself to her constituents, and representation in the U.S. Congress is geographic based rather than issue or ideologically based.
Table 3 gives the results for the over time (2006 to 2007) analysis. Notice that the results change very little from table 2. This indicates that diffusion within state delegations does not have a strong lag. Indeed, much of the dependence in the over time analysis is likely due to the path dependence within individual sites. Once a website adopts a given feature, it is unlikely to remove that feature (authors, 2010 [cite omitted]).

Recall that the model also estimates a structural parameter, $\rho_a$, that captures any dependence that may occur among adjacent congressional districts. If we observe dependence at this level, the model cannot distinguish dependence that might come from causal diffusion processes among the offices in adjacent districts, and a spurious dependence that might come from unobserved confounding variables that vary geographically. The absence of dependence at this level, however, indicated by a $\hat{\rho}_a$ with probability mass near zero, can rule out diffusion as well as the presence of any district level variables that determine the content or quality of websites. We find little to no evidence of dependence at the district level.\textsuperscript{17} For example, in the 2006 cross section, out of the 21 regressions of the first column of table 2, none of the $\hat{\rho}_a$ parameters have a greater than 90 percent chance of exceeding the mean of the prior distribution (0.5), and only three have greater than a 75 percent greater than the prior mean (only the items: casework form, link to FirstGov, and Video), or about what one would expect to observe simply from random variation.

These findings regarding local-level dependence reinforce those from other studies that find relatively few district-level observed variables that are predictive of website quality (Adler, Gent and Overmeyer 1998, 591; Cooper 2004, 352; Druckman, Kifer and Parkin 2007; Druckman et al. 2009, 17; Ferber, Foltz and Pugliese 2005, 147; Authors, 2010). The lack of all dependence at this level further demonstrates the absence of unobserved causal variables. This independence is not especially surprising. Citizens in all districts, whether agricultural or industrial, rich or poor, liberal or conservative, care about maintaining accountability, and make demands for member services. The results show that all members face uniform
incentives driving the quality of websites, and any variation in website quality (as well as responsiveness to social network diffusion) is likely idiosyncratic in the member’s own interest in web technology, along with exposure to such idiosyncrasies in her state delegation.

The model also includes a fixed effect dummy variable, equal to one if the member is a Republican and zero otherwise. Descriptively, we find that Republicans are more likely to have a number of the items on their websites in 2006, including a rationale for their votes, constituent FAQs, a casework form, audio, and a text only feature. Democrats did not have a statistically higher propensity on any of the items. There are any of a number of reasons for this difference between the parties. One set of explanations focus on parties as formal organizations, including a stronger interest among the party leaders in the quality of rank and file websites (Adler, Gent and Overmeyer, 1998, 586), or a difference in the propensity of Republicans and Democrats to take an interest in electronic representation, or the effect of majority party status. Alternatively, one could consider parties to be themselves informal social networks, networks in which web design practices may diffuse. And indeed, as we show in section 2, the offices themselves are most likely to name same-party websites as “especially good.”

The model cannot distinguish explanations based on parties as organizations from parties as social networks, however, for reasons we discuss in footnote 9. We are able to test whether the extent of diffusion within state delegations differs between the two parties. To test this, we re-estimate the model of column one of table 2, changing the likelihood function slightly so that $\rho_s$ is estimated separately for each party. We find only only one (out of 21) of the difference in the $\rho$ parameters for each party were significantly different, or about what one would expect by chance. In addition, the point estimates for the $\rho$ parameter for each party show no consistent pattern, sometimes $\hat{\rho}$ is higher for Democrats, and sometimes for Republicans.

Overall, we find little support for differential party effects, either parties as organizations or parties that organize informal communication among members. Such a finding does not
rule out the presence of within-party diffusion, and indeed, as we note in our descriptive analyses in section 3, the offices themselves suggest otherwise. Instead, we suspect that website design diffuses equally well within each political party.

The outcome equation also includes a fixed effect variable indicating whether the member was a freshman in 2006. This variable also shows little explanatory power, and inconsistent results among the point estimates, with one set of exceptions. Freshmen websites were significantly more likely to be rated highly for navigability, readability, and timeliness. These three variables capture the coders’ qualitative sense of the technical merits of a website. That freshmen are rated higher on these dimensions suggests that 2006 websites have a bit of a slicker design when they are recently created from scratch.

7 Discussion

The above analyses provide insight into the pathways for how online representation practices diffuse within Congress. We find a significant possibility of diffusion within state delegations across a variety of measures of legislative website quality. At the same time, we find little evidence of diffusion in cross-state communication channels driven by substantive policy concerns, cosponsorship networks and ideological proximity. In addition, we find that much of the diffusion is centered on website content, such as issue content and content focused on constituent casework, rather than the communication technology itself.

We find that the underlying communication technology for these websites, such as the presence of blogs, podcasts, RSS feeds, video and the like, is neither driven by district level variables nor by diffusion; we also observe low marginal levels of adoption of various technologies. That offices are not self-reflective or discursive regarding communication technology practices suggests that website technology is a mere afterthought at best. That communication technology exists does not necessarily imply that legislators have the capacity or incentives to adopt them for democratic governance (as in Bimber, 2003; Druckman, Kifer
At the same time, however, we do not detect any geographically distributed, district-level variables that drive website content. Instead, the quality of a legislative website appears to be idiosyncratic across members. Taken together, this suggests that the need for high quality content relevant to legislative representation appears to be mostly driven by the idiosyncrasies among members in a state delegation, rather than a reflection of any variation among localities in demand for good quality websites or stronger online representation. This cohesion in a “small group” is consistent with previous research on social network effects within state delegations (Deckard, 1972; Kessel, 1964; Padgett, 1990; Truman, 1956).

8 Conclusion

These results suggest that much of the communication regarding online representation occurs within state delegations, and this gives some insight into the continued importance of state delegations for the way Congress practices democratic representation. While we cannot state the specific mechanism by which state delegations matter, it may be that offices appear are purposefully learning best practices regarding website content and political communication from each other. In this sense, the results suggest the presence, to some degree, of deliberation among members on the design of the institution itself.

Finally, we note that the methods used in this paper to net out the effects of local level unobservables are general, and could be applied to net out a wide range of confounding variables in any test of behavioral hypotheses in any district-based legislature. We show how to leverage spatial representation in a random effect framework for estimating causal effects, whenever adjacent districts can serve as repeated observations to control for local-level unobservables.
Notes

1In 2006, 72 percent of respondents to the Cooperative Congressional Election Study survey (http://dvn.iq.harvard.edu/dvn/dv/cces) indicated that they would use the official website to discover where their member of Congress stood on issues, compared to only 36 percent indicating they would find this information by calling or writing the office directly; 19 percent from TV news; 7 percent from TV talk shows; 8 percent from radio news; 13 percent from radio talk shows; and 20 percent from newspapers and magazines.

2For example, Walker’s (1969) classic study of the diffusion of innovations among the American states shows that diffusion tends to occur more regularly among adjacent states, which he took to proxy for more regular communication among state-level policymakers (see also Mintrom, 1997).

3At the state level, Caldeira and Patterson (1987) find similar patterns of friendship among Iowa state legislators with districts closer together.

4Arnold, Dean and Al (2000) demonstrate that friendship ties among Ohio state legislators causes members to more often vote on the same side of issues, holding other causes of members’ vote similarity constant.

5Notable exceptions include Baughman (2006), who shows how informal staff communication among members who have overlapping committee assignments reduces the transaction costs for writing and negotiating legislation, and Fowler and Cho (2010), who examine the effects of co-sponsorship networks on legislative productivity; see also Fowler (2006).

6We use these analyses, not as inferential findings, but instead as a summary of but what a large number of staff reported to us regarding their own interpersonal attention networks. We offer a formal inferential test in the next section.

7We also asked about who the Member was friends with, with similar results: of 90 “friends” named, 87 percent were same party, and 44 percent were same state.

8Another potential diffusion network would be “hallway” conversation networks, defined by the physical proximity of offices within office buildings. We found no evidence of this
mechanism in interviews with staff, and preliminary analyses using building and office numbers showed no dependence.

9 For the model we describe in the appendix, one could imagine creating an adjacency matrix where the off diagonal cells equal one if the row and column member are in the same party, and a zero if not, and substituting this matrix for, say, the state delegation matrix. Since parties partition the chamber into two distinct sets of members, the random effect variable $s_i$ at the limit (as the number of members increases in size) will only take on two values, equal to the propensity of all party members to have the item or feature. This random effect then is perfectly collinear with the party variable. Modeling the party using an indicator variable, as we do, or as a social network yield identical results (although on a different scale).

10 The model requires each member to be connected to at least one other member, to avoid dividing by zero. To accommodate this, we assign the few members from states with a single congressional district to an adjacent state that is most similar. It is worth noting that the USGS data from which the district adjacencies are constructed include non-voting delegates from D.C., Puerto Rico and the Virgin Islands, but for some reason not the ones from Guam and American Samoa. Thus, our effective sample is 438 (435 regular members plus three non-voting delegates).

11 Generating the matrix of district adjacencies takes some doing. We downloaded the GIS shapefile of congressional districts for the 109th Congress from the USGS National Atlas website. Unfortunately, this shape file does not represent districts, but instead represents smaller polygons that, when aggregated, reconstruct a congressional district, and obviously adjacencies among these polygons are not of any use for this analysis. Aggregating the data up to the district level turned out to be a very complex task, requiring over a hundred lines of R code. The R script to do this is available from the authors on request.

12 We chose the 12.5 percentile as this kept the density of this adjacency matrix similar to that of the other adjacency matrices.
We also estimated the model including a battery of control variables, and this model yields identical results for the effect of state delegation (both in the point estimates and their precision), a finding that lends confidence to the random effect approach that we adopt. Specifically, we re-estimated the model for national issues content, but this time including variables indicating whether the member was a party leader or committee chair; the member’s vote margin in the previous election; and the district’s percent white, average income, percent over 64, percent under 18, and percent college educated. None of these covariates show significant effects nor large point estimates, with the exception of the leadership variable. Excluding this variable does not bias our findings, however, since the number of leaders is a tiny fraction of the dataset. We report only results from our two control variable model since this model converges much more readily.

Members gain greater electoral security with longer tenure in office due to the well-known incumbent advantages (Jacobson, 1987, 26). Members with longer tenures in office have fewer incentives to seek out innovative ways to interact with constituents through their websites than those with shorter tenures. Members with longer tenures also are more likely to have well-established ways of communicating with constituents (Arnold, 2004) and thus are unlikely to place much effort in this new form of legislative communication.

To improve convergence, we use an informative uniform on [-1,1] prior. This should have no effect on the results since we only care about the existence of dependence in these models, not the magnitude.

The $\rho_s$ parameter in each case is statistically significant, but only because the impact of state delegation is only to move a member from a zero probability to something slightly larger than zero.

This is true whether or not we include the state delegation grouping in the model.

To do this, we modify the model in the appendix by specifying the right hand side of the equation for $\bar{s}_i$ as $\rho_{s,\text{rep}} \cdot \sum_{k=1}^{N_s,i} (W_{sk})/(N_{si}) \times \text{Republican} + \rho_{s,\text{dem}} \cdot \sum_{k=1}^{N_s,i} (W_{sk})/(N_{si}) \times (1 - \text{Republican})$. 
References

Appendices

In this section, we describe the statistical model, and we discuss the reliability and validity of the website coding.

A Statistical Model

Our statistical model is designed to test the effect of membership in a state delegation by holding constant local level variables that might spuriously drive dependence among delegation members’ websites. We do this by exploiting district adjacency data to estimate and hold constant a district-level random effect. The basic statistical model is:

\[
\begin{align*}
O_i & \sim \text{Categorical}(p_{i,1...5}) \\
p_{i,1} &= 1 - q_{i,1} \\
p_{i,2} &= q_{i,1} - q_{i,2} \\
p_{i,3} &= q_{i,2} - q_{i,3} \\
p_{i,4} &= q_{i,3} - q_{i,4} \\
p_{i,5} &= q_{i,4} \\
\text{logit}(q_{i,1}) &= b_1 \cdot \text{Freshman}_{1,i} + b_2 \cdot \text{Republican}_{2,i} + a_i + s_i - \kappa_1 \\
\text{logit}(q_{i,2}) &= b_1 \cdot \text{Freshman}_{1,i} + b_2 \cdot \text{Republican}_{2,i} + a_i + s_i - \kappa_2 \\
\text{logit}(q_{i,3}) &= b_1 \cdot \text{Freshman}_{1,i} + b_2 \cdot \text{Republican}_{2,i} + a_i + s_i - \kappa_3 \\
\text{logit}(q_{i,4}) &= b_1 \cdot \text{Freshman}_{1,i} + b_2 \cdot \text{Republican}_{2,i} + a_i + s_i - \kappa_4 \\
a_i & \sim \phi(\bar{a}_i, 1) \\
\bar{a}_i &= \rho_a \cdot \sum_{k=1}^{N_{ai}} (W_{aik})/(N_{ai}) \\
N_{ai} &= \# \{a_j : j \text{ is adjacent to } i\} \\
W_{aik} &\in \{a_j : j \text{ is adjacent to } i\} \\
s_i & \sim \phi(\bar{s}_i, 1) \\
\bar{s}_i &= \rho_s \cdot \sum_{k=1}^{N_{si}} (W_{sik})/(N_{si}) \\
W_{sik} &\in \{O_j : j \text{ is in the same state delegation as } i\} \\
N_{si} &= \# \{s_j : j \text{ is in the same state delegation as } i\}
\end{align*}
\]
\[
\begin{align*}
\rho_a & \sim \text{Uniform}(0, 1) \\
\rho_s & \sim \text{Uniform}(-100, 100) \\
b_1 & \sim \phi(0.0, 1.0E-5) \\
b_2 & \sim \phi(0.0, 1.0E-5) \\
\kappa_1 & \sim \phi(-1, 0.1)C(-5, k_2) \\
\kappa_2 & \sim \phi(-0.5, 0.1)C(k_1, k_3) \\
\kappa_3 & \sim \phi(0.5, 0.1)C(k_2, k_4) \\
\kappa_4 & \sim \phi(1, 0.1)C(k_3, 5)
\end{align*}
\]

We estimate the model separately for each dependent variable, \(O_i\), listed in table 1. The set of equations contained within the outermost bracket gives the model likelihood for a five category ordered dependent variable; the dichotomous outcome variables are also ordered so for these items we use the same equation but estimate only one threshold. The conditional probability of each outcome is taken to be a function of the two fixed effect control variables, Term and Republican, their estimated coefficients, \(b\), a category-specific threshold \(\kappa_j\), and the two random intercepts, \(a_i\) and \(s_i\).

In the model, \(a_i\) is a random effect that captures local-level unobservables, and \(s_i\) is a random effect that captures dependence in each outcome variable among members of a state delegation holding \(a_i\) constant. Inference for the social network effects are based on the parameter \(\rho_s\), which is given a diffuse prior;\(^{19}\) \(\rho_s\) is the effect of a change in the propensity of a member’s website to have a design feature \((O_i)\) associated with the propensity of the websites of those that are in the member’s state delegation to have the feature or characteristic. As we discuss above, because we control for district level heterogeneity via \(a_i\), \(\rho_s\) captures the causal dependence among the websites of members within a state delegation. The random intercept \(a_i\) is assumed to have a normal prior, with mean a function of the random intercepts of the member’s district adjacency set (this is known as a CAR prior, (see Congdon, 2003, chapter 7)). The random intercept \(s_i\) is assumed to have a normal prior, with mean a function of the outcomes \((O_i')\) of the member’s state delegation.

For the spatial statistical models, it is possible for the precision of estimated correlation parameters to be a function of the average density of the adjacency matrix, where the average density is the total number of ones divided by the number of matrix cells. The
average density of the state delegation adjacency matrix is 0.042, while the average density of the district adjacency matrix is 0.023. To test the robustness of our results below to variation in network density, we constructed a supplemented district adjacency matrix that equals one if two districts are either adjacent to each other or are within one district of each other (i.e., on a two step path). The average density of this supplemented district adjacency matrix is 0.064. Thus the two district adjacency matrices create density bounds below and above the state delegation density. In the estimates we find little difference (point estimates and their precision) for district adjacency across these two distance measures, so to simplify the discussion we only present the results on the former, single-step adjacency matrix.

B Coding Reliability

Because the data come from two different years, we must assess intercoder reliability both within each year as well as across the two years. There were a total of 8 coders involved in each year. Each coder evaluated ten common web sites in each of the two years. Coders received extensive training and then evaluated all web sites in a randomized order, not knowing which ten web sites were the common web sites. The error rates within each year were very low across the items, ranging from as low as 8.2 percent to as high as 15.0 percent, when one would expect about a 50 percent error rate by chance. To assess over time reliability, two of the coders happened to participate in each year’s coding effort. In the 2007 coding, we asked these two coders to code an additional ten websites that were archived from 2006. The error rates never exceeded 20 percent across the items. On only one item (out of over 100 items) did there appear to be a drift in the standard for evaluation between the two years, where both coders rated one item (vote rationales) slightly higher in 2006 than in 2007. Overall, the within year and over time reliability of these data appear to be good, reflecting the extensive training each coder received.
C Coding Validity

The statistical model of dependence within state delegations that we use helps to net out any spurious dependence among geographically-proximate units by holding constant local level variables (via a random effect). This method, however, cannot account for spurious dependence that arises from the coding process itself. In the data collection coders were randomly assigned to evaluate websites. Because of this, idiosyncratic biases of the coders could not drive the state-level dependence we observe in tables 2 and 3. But it is possible that all coders share some bias or biases in response to observable traits or characteristics of the websites. For example, perhaps coders had predispositions that northeastern or west coast websites are more sophisticated than southern or midwestern websites. While these predispositions should not affect the objective codes, such as the presence of certain types of links or audio, they could affect the subjective ratings of the quality of the issue content, the navigability, readability, and so on.

To address this, we developed a test for the presence of these biases. In this test, we use objective features of websites to hold the quality of the website, and then test for whether gender, party and regional difference remain. These latter covariates should be uncorrelated with the subjective coder ratings, holding constant the website’s objective quality. To conduct this validity test we first created one factor using the objective codes for constituent interest content (constituent FAQs, help with casework initiation, a casework form, links to federal agencies, link to FirstGov.gov, grant information on district resources), and another factor using the objective codes for the technical features of the website (video, audio, text only, blog, rss feed, and podcast). We regressed these two factors, along with indicators for the member’s gender and political party and Census region (NE, MW, S, W), on the subjective coding measures: Navigation, Timeliness, and Readability. None out of 18 (6 × 3) tests were significant for region; gender and political party were not significant at in any equation (although both came close to significance for timeliness).

We also regressed these factors and fixed variables on a factor constructed from the issue
ratings (national issues, member’s issues, state/local issues and vote rationales). In this latter test, there were slight differences by region in the rated quality of the website’s issue content (the midwestern sites were rated as slightly lower than those in the northeast and the west), but this may not indicate bias in the codings, since there may indeed be differences in issue content among the regions even after netting out the constituent and technology factors. If biases were to appear in the issue content, it would most likely be due to the coder’s own subjective disagreement with the content itself; neither party nor gender were significant in the issue ratings equation, however, suggesting these biases were not at work.
